- Agents don't have complete knowledge about the world.
- Agents need to make decisions in an uncertain world.
- It isn't enough to assume what the world is like. Example: wearing a seat belt.
- An agent needs to reason about its uncertainty.
- When an agent acts under uncertainty, it is gambling.
- Agents who don't use probabilities will do worse than those who do.

- Belief in a proposition  $a$  can be measured by a number between 0 and 1 — this is the *probability of  $a$*   $= P(a)$ .
  - $P(a) = 0$  means that  $a$  is believed false.
  - $P(a) = 1$  means that  $a$  is believed true.
- $0 < P(a) < 1$  means the agent is unsure.
- Probability is a measure of ignorance.
- Probability is *not* a measure of degree of truth.

- The variables in probability are called *random variables*.
- Each variable  $X$  has a set of possible values.
- A tuple of random variables is written as  $X_1, \dots, X_n$ .
- $X = x$  means variable  $X$  has value  $x$ .
- A *proposition* is a Boolean expression made from assignments of values to variables.
- Example:  $X_1, X_2$  are the values of two dice.  $X_1 + X_2 = 7$  is equivalent to  $(X_1 = 1 \wedge X_2 = 6) \vee (X_1 = 2 \wedge X_2 = 5) \vee \dots$

- A *possible world*  $\omega$  is a variable assignment (all the variables).
- Let  $\Omega$  be the set of all possible worlds.
- Assuming each variable has a finite set of possible values.
  - Define  $P(\omega)$  for each world  $\omega$  so that  $0 \leq P(\omega)$  and they sum to 1.  
This is the *joint probability distribution*.
  - The probability of proposition  $a$  is defined by:

$$P(a) = \sum_{\omega \models a} P(\omega)$$

- Markov Models

Three axioms for probabilities (finite case)

1.  $0 \leq P(a)$  for any proposition  $p$ .
2.  $P(a) = 1$  if  $a$  is a tautology.
3.  $P(a \vee b) = P(a) + P(b)$  if  $a$  and  $b$  contradict.

For all propositions  $a$  and  $b$ , these axioms imply:

- $P(\neg a) = 1 - P(a)$
- $P(a \vee b) = P(a) + P(b) - P(a \wedge b)$
- $P(a) = P(a \wedge b) + P(a \wedge \neg b)$
- If variable  $V$  has possible values  $D$ , then
$$P(a) = \sum_{d \in D} P(a \wedge V = d)$$

- Conditional probabilities specify how to revise beliefs based on *evidence*, known values for one or more variables.
- If  $e$  is the evidence, the *conditional probability* of  $h$  given  $e$  is  $P(h | e) = P(h \wedge e) / P(e)$ .
- Chain Rule:  $P(a \wedge b \wedge c) = P(a | b \wedge c)P(b \wedge c) = P(a | b \wedge c)P(b | c)P(c)$
- Bayes' Theorem:  
 $P(h | e) = P(e | h)P(h) / P(e)$
- Update with additional evidence  $e'$ .  
 $P(h | e \wedge e') = P(e' | h \wedge e)P(h | e) / P(e' | e)$

Probability

Conditional  
Independence

▷ Lots of Small  
Numbers

Conditional  
Independence

Naive Bayes

Bayesian Networks

Algorithms

Markov Models

- If there are  $n$  binary variables, there are  $2^n$  numbers to be assigned for a joint probability distribution.
- They need to add up to one, so if  $2^n - 1$  numbers are assigned, the last one can be solved for. [Doesn't help much.]
- In addition, each number is likely to be very, very small, so it is unrealistic to use frequencies (even with Big Data).
- Reduce work by using knowledge of when one variable is independent of another variable.

# Conditional Independence

Probability

Conditional Independence

Lots of Small Numbers

▷ Conditional Independence

Naive Bayes

Bayesian Networks

Algorithms

Markov Models

- $X$  and  $Y$  are *independent* if, for any  $x, y$ ,  
$$P(X = x \wedge Y = y) = P(X = x)P(Y = y).$$
  - One die is independent of the other die.
  - Rain is independent of the day of the week.
- $X$  is *conditionally independent* of  $Y$  given  $Z$  if  
$$P(X = x \mid Y = y \wedge Z = z) = P(X = x \mid Z = z)$$
for any  $x, y, z$ . Knowing  $Z$ , ignore  $Y$  to infer  $X$ .
  - A nice day ( $Y$ ) makes me more likely to exercise ( $Z$ ), and so more likely to be tired ( $X$ ).
  - Suppose  $X, Y, Z$  randomly chosen, but  $X \neq Z$  and  $Z \neq Y$ .

# Naive Bayes

Probability

Conditional Independence

Lots of Small Numbers  
Conditional Independence

▷ Naive Bayes

Bayesian Networks

Algorithms

Markov Models

- Suppose we want to determine the probability of a hypothesis given the evidence
- A naive, but often effective, assumption is that the evidence is conditionally independent of the hypothesis.

$$\begin{aligned} P(H \mid E_1, \dots, E_n) \\ &= P(H) P(E_1, \dots, E_n \mid H) / P(E_1, \dots, E_n) \\ &\approx P(H) \prod_{i=1}^n P(E_i \mid H) / P(E_1, \dots, E_n) \end{aligned}$$

- Different values for  $H$  have same denominator, so only need to compare numerators.

Construction

Algorithms

Markov Models

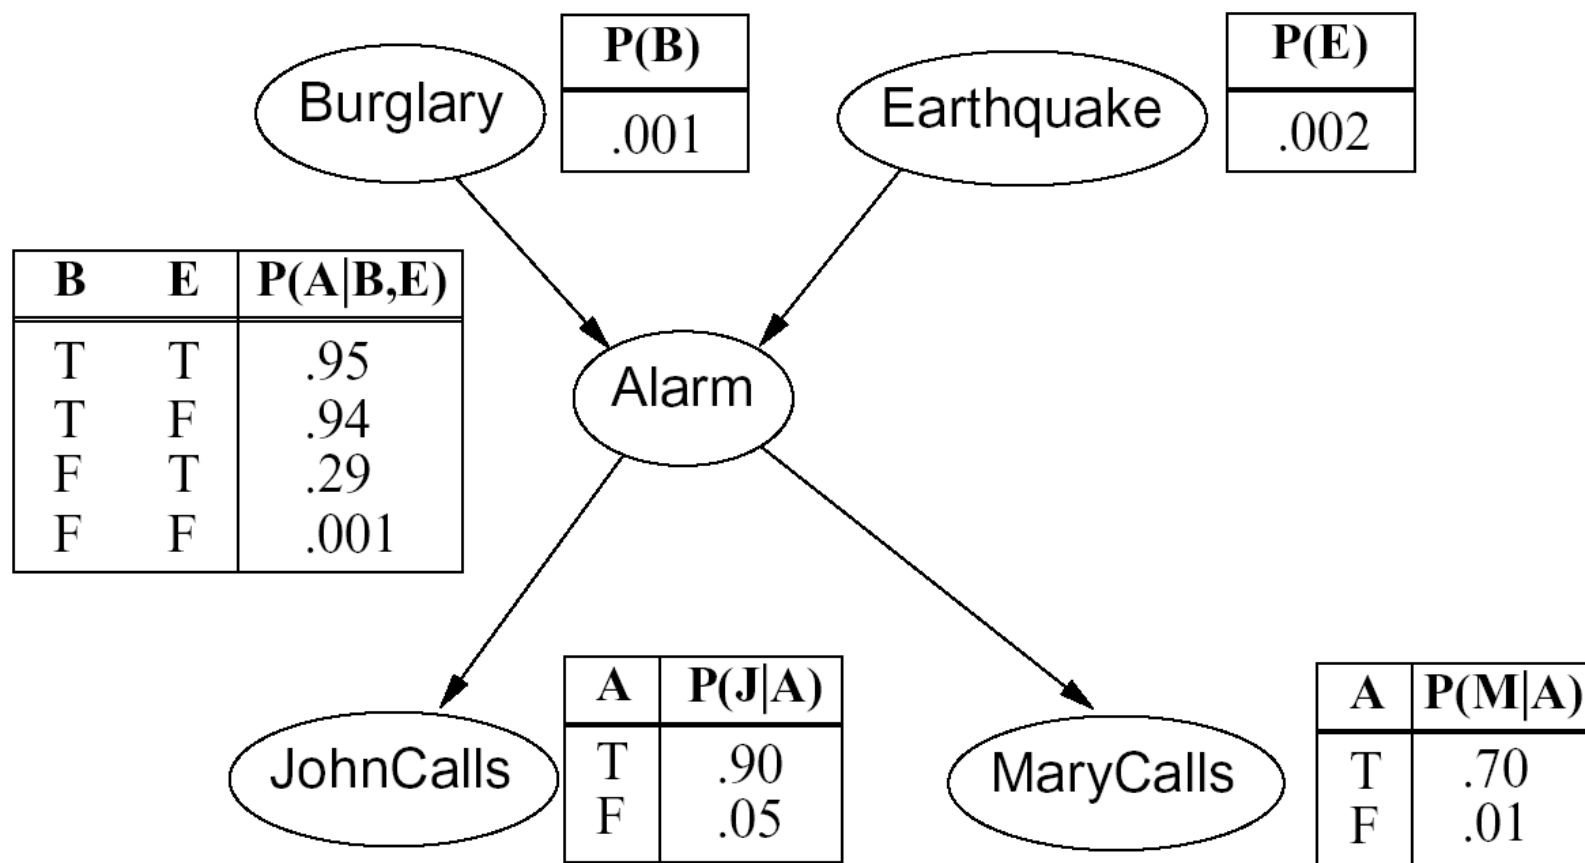

A *Bayesian network*\* consists of:

- a directed acyclic graph, where nodes correspond to variables,
- a set of possible values for each variable,
- a prior probability table for each variable with no parents, and
- a conditional probability table for each variable with parents, specifying the probability of the variable given its parents.

\*I prefer “Bayesian network” over “belief network”.

To represent a problem in a Bayesian network:

- What are the relevant variables?
  - What will you observe?
  - What would you like to infer?
  - Are there hidden variables that would make the model simpler?
- What are the possible values of the variables?
- What is the relationship between them? A cause should be a parent of what it directly affects.
- How does the value of each variable depend on its parents, if any? This is expressed by prior and conditional probabilities.

Variable elimination is an exact algorithm for computing  $P(h | e)$ . Assume  $h$  is one variable.

- Convert each probability table into a *factor*. Let  $F$  be all the factors.
- Eliminate each non-query variable  $X$  in turn:
  - Identify the factors  $F'$  in which  $X$  appears.
  - If  $X$  is observed, *set*  $X$  to the observed value in each factor in  $F'$ .
  - Otherwise, *multiply* the factors in  $F'$  together, *sum out*  $X$ , add the result to  $F$ , and remove  $F'$  from  $F$ .
- *Multiply* the remaining factors and *normalize*.

HMM Probabilities

A *Markov chain* is a Bayesian network for representing a sequence of values.

- This represents the *Markov assumption*:  
$$P(S_{t+1} \mid S_0, \dots, S_t) = P(S_{t+1} \mid S_t)$$
- A *stationary* Markov chain has  
$$P(S_{t+1} \mid S_t) = P(S_1 \mid S_0)$$
- Sequence of states over time, e.g., queueing theory.
- Probability of next item (word, letter) given previous item.

Hidden Markov Models

HMM Probabilities

A *hidden Markov model* adds observations to a Markov chain.

- States are not directly observable.
- Observations provide evidence for states.
- $P(S_0)$  specifies initial conditions.
- $P(S_{t+1} | S_t)$  specifies the dynamics.
- $P(O_t | S_t)$  specifies the sensor model.

    - ▷ Probabilities

- To compute  $P(S_i | O_0, \dots, O_i, \dots, O_k)$ 
  - Compute variable elimination forward. This computes  $P(S_i | O_0, \dots, O_{i-1})$ .
  - Compute variable elimination backward. This computes  $P(O_i, \dots, O_k | S_i)$ .
  - $P(S_i | O_0, \dots, O_k) \propto P(S_i | O_0, \dots, O_{i-1}) * P(O_i, \dots, O_k | S_i)$
- To compute most probable sequence of states:
  - Viterbi algorithm.
  - Idea: Find most probable sequence to  $S_i$ .
  - Use that information to extend sequence by one state, and repeat.
