ABSTRACT
The Internet is a man-made complex system under constant attacks (e.g., Advanced Persistent Threats and malwares). It is therefore important to understand the phenomena that can be induced by the interaction between cyber attacks and cyber defenses. In this paper, we explore the rich phenomena that can be exhibited when the defender employs active defense to combat cyber attacks. To the best of our knowledge, this is the first study that shows that active cyber defense dynamics (or more generally, cybersecurity dynamics) can exhibit the bifurcation and chaos phenomena. This has profound implications for cyber security measurement and prediction: (i) it is infeasible (or even impossible) to accurately measure and predict cyber security under certain circumstances; (ii) the defender must manipulate the dynamics to avoid such unmanageable situations in real-life defense operations.

Categories and Subject Descriptors

General Terms
Security, Theory

Keywords
Active cyber defense, active cyber defense dynamics, cyber attack-defense dynamics, cybersecurity dynamics, cyber security models

1. INTRODUCTION
Malicious attacks in cyberspace will remain to be a big problem for the many years to come. This is fundamentally caused by the complexity of the Internet and computer systems (e.g., we cannot assure that a large software system has no security vulnerabilities). It is therefore important to understand and characterize the phenomena that can be exhibited at the global level of a cyber system, ranging from an enterprise network to the entire cyberspace. The emerging framework of Cybersecurity Dynamics [34, 35, 7, 4] offers a systematic approach for understanding, characterizing, and quantifying the phenomena as well as cyber security in general. The current generation of cyber defenses is often based on reactive tools that are known to have limited success. For example, infected/compromised computers cannot be cleaned up even by using multiple anti-malware tools together [21]. Moreover, reactive defense has a fundamental limitation, namely that the effect of attacks is automatically amplified by network connectivity, but the effect of reactive defenses is not. This attack-defense asymmetry had been implied by studies such as [29, 6, 3, 28, 39], but was not explicitly pointed out until [36].

One approach to overcoming the aforementioned attack-defense asymmetry is to adopt active cyber defense, which is to use the same mechanism that is exploited by attackers. More specifically, active defense aims to spread some “white” worms (called defenseware in this paper) to automatically identify and “kill” the malicious malwares in compromised/infected computers [2, 1, 30, 26, 16, 18, 14, 31]. In some sense, active cyber defense already takes place in cyberspace because (for example) the malware called Welchia attempts to “kill” the malware called Blaster in compromised computers [26, 22], but it may take some years for full-scale active cyber defenses to arise [18, 27, 32]. The first mathematical model for studying the global effectiveness of active cyber defense has been proposed recently [36]. In this paper, we further the study of active cyber defense dynamics from a new perspective.

Our contributions. We substantially extend some aspects of the first mathematical model of active cyber defense dynamics [36] (to be fair, we should note that [36] offers some perspectives that are not considered in our model as well). The extensions can be characterized as follows. First, we accommodate more general attack-power and defense-power functions, meaning that our results are applicable to a broader setting than what is investigated in [36]. Second, we allow the attack network structure to be different from the defense network structure, which are assumed to be identical in [36]. This is important and realistic because the attack-defense interaction structures are often “overlay” networks on top of some physical networks, and as such, the defender and the attacker can use different structures based on their own defense/attack strategies.

The extended model allows us to explore the rich phenomena that can be exhibited by active cyber defense dynamics. Specifically, we show that active cyber defense dynamics can exhibit the bifurcation and chaos phenomena (we call them unmanageable situations in cyber security). To the best of our knowledge, this is the first study that shows that bifurcation and chaos are relevant in the cyber security domain. These phenomena indicate limitations on the measurement and prediction of cyber security, and highlight that cyber defenders must manipulate the (active) cyber defense dynamics to avoid such unmanageable situations in real-life cyber defense operations.
Disclaimer. The active cyber defense strategy explored in the present paper does not advocate that defenders should retaliate from attackers, because it is well known that the attackers, or more precisely the IP addresses that are launching attacks against the victims, could well be victims that are abused by the real attackers as stepping stones. Moreover, defenses are (i.e., “white” worms) are meant to clean up the compromised computers, not to compromise the secure computers. Most important of all, the active defense operations should be contained within the networks under the defender’s jurisdiction (e.g., an enterprise network defender may use active defense to clean up the enterprise network but not going beyond the enterprise’s perimeter). This can be assured, for example, by making the enterprise’s computers and firewalls recognize defenses via digital signatures. This means that the enterprise computers will only run defenses that are accompanied with digital signatures that can be verified by the computers’ hardware via an embedded signature verification key, and that the firewall recognizes and blocks out-bound defenses.

The rest of the paper is organized as follows. In Section 2, we present our active cyber defense dynamics model. In Section 3, we analyze equilibria (or attractors) of active cyber defense dynamics. In Section 4, we explore the transition between attractors. In Section 5, we investigate the emergence of bifurcation. In Section 6, we analyze equilibria (or attractors) of active cyber defense dynamics. In Section 7 and conclude the paper in Section 8.

| $\mathbb{R}$, $\mathbb{R}^+$, $\mathbb{C}$ | the sets of real numbers, positive real numbers and complex numbers, respectively |
| $\mathbb{R}(\omega)$, $\Im(\omega)$ | the real and imaginary parts of complex number $\omega \in \mathbb{C}$, respectively |
| $I_n$ | the $n \times n$ identity matrix |
| $G_B$, $A_B$ | $G_B = (V,E_B)$ is the defense network structure, and $A_B$ is the adjacency matrix of $G_B$ |
| $G_R$, $A_R$ | $G_R = (V,E_R)$ is the attack network structure, and $A_R$ is the adjacency matrix of $G_R$ |
| $N_v,G'_v$ | $N_v,G'_v = \{u \in V' : (u,v) \in E'\}$ is the neighbors of $v$ in graph/network $G' = (V',E')$ |
| $\deg(v,G')$ | $\deg(v) = |N_v|$ is node $v$’s in-degree in graph/network $G' = (V',E')$ |
| $D_{A'}$ | $D_{A'} = [d_{uv}]_{n \times n}$ is a diagonal matrix corresponding to adjacency matrix $A' = [a'_{uv}]_{n \times n}$, where $d_{uv} = \sum_{t=1}^{n} a_{uv}$ is the in-degree of node $v$ in graph $G'$ corresponding to $A'$ |
| $\lambda(M)$ | the set of eigenvalues of matrix $M$ |
| $\lambda_1(M)$ | the eigenvalue of $M$ with the largest real part (or $\lambda_1$ when $M$ is clear from the context) |
| $B_v(t), R_v(t)$ | the probability that node $v \in V$ is in state blue (i.e., secure) and state red (i.e., compromised) at time $t$, respectively |
| $\langle B_v(t) \rangle$ | the average portion of blue nodes at time $t \geq 0$, namely $(B_v(t)) = \frac{1}{|V|} \sum_{v \in V} B_v(t)$ |
| $B(t), R(t)$ | $B(t) = [B_1(t), \ldots, B_n(t)], R(t) = [R_1(t), \ldots, R_n(t)]$, where $n = |V| |
| $B^*$ | the homogeneous equilibrium of $B(t)$ as $t \to \infty$, namely $B_v(t) = \sigma \forall v \in V$ as $t \to \infty$ |
| $f(\cdot), g(\cdot)$ | $f(\cdot) : [0,1] \to \{0\} \cup \mathbb{R}^+$ is the defense-power function, and $g(\cdot) : [0,1] \to \{0\} \cup \mathbb{R}^+$ is the attack-power function |
| $\theta_{v, BR}(t)$ | the probability that the state of node $v$ changes from blue to red at time $t$ |
| $\theta_{v, RB}(t)$ | the probability that the state of node $v$ changes from red to blue at time $t$ |

2. EXTENDED ACTIVE CYBER DEFENSE DYNAMICS MODEL

Review of the model in [36]. Suppose attacker and defender interact in a cyber system that consists of a finite node population $V = \{1,2, \ldots, n\}$, where each node can abstract/represent a computer. At any time $t \geq 0$, a node $v \in V$ is in one of two states: blue, meaning that the node is secure but vulnerable to attacks; red, meaning that the node is compromised. For a given cyber system, the attacker spreads computer malwares (e.g., Advanced Persistent Threats) to compromise computers, while the defender spreads defenses (e.g., “white” worms) to detect and clean up (or “cure”) the compromised computers. Suppose both the malwares and the defenses spread over the same attack-defense network structure, namely a finite simple graph $G = (V,E)$, where $V = \{1,2, \ldots, n\}$ is the vertex set mentioned above, and $E$ is the edge set such that $(u,v) \in E$ means (i) a compromised node $u$ can attack a secure node $v$ and (ii) a secure node $u$ can use active defense to detect and clean up a compromised node $v$.

Our extension to the model in [36]. Rather than assuming the attacker and defender use the same attack-defense network structure, we consider two network structures: the defense network structure $G_D = (V,E_D)$ over which defenses spread, and the attack network structure $G_R = (V,E_R)$ over which malwares spread. Both network structures are directed or undirected graphs. Specifically, $(u,v) \in E_D$ means a secure node $u$ can use active defense to “cure” a compromised node $v$, and $(u,v) \in E_R$ means a compromised node $u$ can attack a secure node $v$. We do not make any restrictions on the attack/defense network structures, except that we assume $G_D$ and $G_R$ are simple graphs with no self-edges.1 For the purpose of illustrating results, we will use random graphs as concrete examples though.

Denote by $A_B = [a_{uv}]_{n \times n}$ the adjacency matrix of $G_B$ where $a_{uv} = 1$ if and only if $(u,v) \in E_B$. Denote by $A_R = [a_{uv}]_{n \times n}$ the adjacency matrix of $G_R$ where $a_{uv} = 1$ if and only if $(u,v) \in E_R$. Note that the representation accommodates both directed and undirected graphs. Denote by $B_v(t)$ and $R_v(t)$ the probability that node $v \in V$ is in state blue (i.e., secure) and state red (i.e., compromised) at time $t$, respectively.

\[ \begin{align*}
\frac{dB_v(t)}{dt} &= \theta_{v, BR}(t) \cdot R_v(t) - \theta_{v, RB}(t) \cdot B_v(t) \\
\frac{dR_v(t)}{dt} &= \theta_{v, RB}(t) \cdot B_v(t) - \theta_{v, BR}(t) \cdot R_v(t)
\end{align*} \]

(1)

In order to specify $\theta_{v, BR}(t)$, we use the concept of defense-power function $f(\cdot) : [0,1] \to \{0\} \cup \mathbb{R}^+$, which abstracts the...

---

1It is possible to accommodate privilege escalation in the present model, by treating a computer as a set of nodes that correspond to different privileges. We leave the details to future investigation.
power of the defenseware in detecting and cleaning up compromised (red) nodes. In order to specify \( \theta_{v, BR}(t) \), we use the concept of attack-power function \( g(\cdot) : [0, 1] \to \{0, 1\} \cup \mathbb{R}^+ \), which abstracts the power of the malware in compromising secure (blue) nodes. It is intuitive that both defense-power and attack-power functions should be dependent on the defense and attack network structures, respectively. Therefore, we have the following general form:

\[
\theta_{v, RB}(t) = f \left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) \right),
\]

\[
\theta_{v, BR}(t) = g \left( \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} B_u(t) \right)
\]

where \( N_v, G_B = \{ u : (u, v) \in E_B \} \) is the set of node \( v \)'s neighbors in graph \( G_B \) and \( N_v, G_R = \{ u : (u, v) \in E_R \} \) is the set of node \( v \)'s neighbors in graph \( G_R \).

For the present characterization study, it is sufficient to require that the defense-power and attack-power functions possess some basic properties. First, we have \( f(0) = 0 \) because active defense must be launched from some blue node, and \( g(1) = 0 \) because attack must be launched from some red node. Second, we have \( f(x) > 0 \) for \( x \in [0, 1] \) because any active defense may succeed, and \( g(x) > 0 \) for \( x \in [0, 1] \) because any attack may succeed. Third, the two functions do not have to abide by any specific relation, except that they are differentiable (for the sake of analytic treatment).

As a result, the master equation of active cyber defense dynamics, namely Eq. (1), becomes:

\[
dB_u(t) = f \left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) \right) R_u(t) - g \left( \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} B_u(t) \right) B_u(t)\]

\[
dR_u(t) = g \left( \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} B_u(t) \right) B_u(t) - f \left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) \right) R_u(t).
\]

Since \( \frac{dB_u(t)}{dt} + \frac{dR_u(t)}{dt} = 0 \) holds for all \( t \geq 0 \) and all \( v \in V \), \( B_u(t) + R_u(t) = 1 \) for all \( t \) and all \( v \in V \). Therefore, we only need to consider the following master equation for \( v \in V \):

\[
dB_u(t) = f \left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) \right) \left[ 1 - B_u(t) \right] - g \left( \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} B_u(t) \right) B_u(t).
\]

The main research task is to analyze system (2) for all \( v \in V \).

**Remark.** When we investigate specific attacks and defenses, we need to obtain their concrete attack-power and defense-power functions. Similarly, when we investigate specific cyber systems, we need to obtain the concrete attack and defense network structures. These are important research problems that are orthogonal to the focus of the present paper because our characterization study deals with all possible attack-power and defense-power functions as well as all possible attack and defense network structures. In principle, these functions and structures do exist, although how to obtain them is an excellent problem for future investigation.

3. EQUILIBRIA AND THEIR STABILITY

Equilibrium is an important concept for quantifying cyber security. Suppose \( \sigma \) is the equilibrium under certain active defense. We can quantify the effectiveness of active defense via the notion of \( \sigma \)-effectiveness because the dynamics converge to \( \sigma \). Moreover, the stability of an equilibrium reflects the consequence/effect of perturbations, which can be caused (for example) by manipulations to the initial global state (e.g., the defender manually cleans up some compromised computers before launching active defense for more effectiveness — this may sound counterintuitive, but it actually shows the value of rigorous characterization study because the defender would not know this tactics otherwise).

We consider a class of equilibria of Eq. (2), namely homogeneous equilibria \( \{B^1, \ldots, B^n\} \) with \( B^1 = \cdots = B^n = \sigma = \sigma(0, 1] \). This class contains the following:

- All-blue equilibrium, denoted by \( B^* = 1 \); \( B^*_v = 1 \) for all \( v \in V \) (i.e., active defense is 1-effective).
- All-red equilibrium, denoted by \( B^* = 0 \); \( B_v^* = 0 \) for all \( v \in V \) (i.e., active defense is 0-effective).
- \( \sigma \)-equilibrium, denoted by \( B^* = \sigma \); \( B^*_v = \sigma \) for all \( v \in V \) (i.e., active cyber defense is \( \sigma \)-effective).

The Jacobian matrix of (2) near an equilibrium is denoted by

\[
M = \left[ (1 - \sigma) f'(\sigma) D_{A_B}^{-1} A_B - \sigma g'(\sigma) D_{A_R}^{-1} A_R \right] - \left[ f(\sigma) + g(\sigma) \right] I_n.
\]

3.1 Existence and Stability of Equilibria

We show that homogeneous equilibria exist under the following hypothesis (or condition):

**H_0:** there exists some \( \sigma \in [0, 1] \) such that \( (1 - \sigma) \cdot f(\sigma) = \sigma \cdot g(\sigma) \) holds.

**PROP 1.** Under hypothesis **H_0**, \( B^* = \sigma \in [0, 1] \) is an equilibrium of (2). Moreover, \( B^* \) is stable if \( \Re(\mu) < 0 \) for all \( \mu \in \lambda(M) \), and unstable if \( \Re(\mu) > 0 \) for some \( \mu \in \lambda(M) \).

**PROOF.** Under hypothesis **H_0**, namely \( (1 - \sigma) \cdot f(\sigma) = \sigma \cdot g(\sigma) \), we see that \( B^*_v = \sigma \) satisfies

\[
\frac{dB_v(t)}{dt} = (1 - \sigma) \cdot f(\sigma) - \sigma \cdot g(\sigma) = 0, \quad \forall v \in V.
\]

Thus \( B^* = \sigma \) is an equilibrium.

To see the stability of equilibrium \( B^* = \sigma \in [0, 1] \), we consider a small perturbation to \( B^* \), namely \( \delta B = [B_1 - B_1^*, \ldots, B_n - B_n^*] \). The linearization system of Eq. (2) near \( B^* \) leads to

\[
\frac{d\delta B}{dt} = \left\{ \left[ (1 - \sigma) f'(\sigma) D_{A_B}^{-1} A_B - \sigma g'(\sigma) D_{A_R}^{-1} A_R \right] - \left[ f(\sigma) + g(\sigma) \right] I_n \right\} \delta B,
\]

where \( I_n \) is the identity matrix of size \( n \). Note that \( M \) as defined in Eq. (3) is the coefficient matrix of linear system (4). The stability of equilibrium \( B^* = \sigma \) is determined by the eigenvalues of matrix.
M. For the general case $G_B = (V, E_B) \neq G_R = (V, E_R)$, it can be shown that
\[
\lambda(M) = \lambda \left( (1 - \sigma)f'(\sigma)D_{A^1}A_B - \right.
\sigma g'(\sigma)D_{A_R}A_R - \left[ f(\sigma) + g(\sigma) \right].
\]
(5)
If $\mathbb{R}(\mu) < 0$ for all $\mu \in \lambda(M_0)$, $B^* = \sigma$ is locally stable; if $\mathbb{R}(\mu) > 0$ for some $\mu \in \lambda(M)$, $B^* = \sigma$ is locally unstable.

Proposition 1 can be simplified when $\sigma = 0$ and $\sigma = 1$.

**Corollary 1.** If $g(1) = 0$, then $B^* = 1$ is an equilibrium. It is locally stable if $-g'(1) < f(1)$ and locally unstable if $-g'(1) > f(1)$.

If $f(0) = 0$, then $B^* = 0$ is an equilibrium. It is locally stable if $f'(0) < g(0)$ and locally unstable if $f'(0) > g(0)$.

**Proof.** To prove the first part, we observe that $g(1) = 0$ implies $H_0$ holds for $\sigma = 1$, namely that $B^* = 1$ is an equilibrium of system (2). For $\sigma = 1$, it can be shown that Eq. (4) becomes
\[
\frac{d\delta B}{dt} = \left[ -g'(1)D_{A_R}^1A_R - f(1)I_0 \right] \delta B.
\]
Proposition 1 says that a sufficient condition under which equilibrium $B^* = 1$ is locally stable is
\[
-g'(1)\mathbb{R}(\mu) < f(1), \quad \forall \mu \in \lambda(D_{A_R}^1A_R).
\]
(6)
Since $g(1) = 0$ and $g(x) \geq 0$ for $x \in [0, 1]$, $g(x)$ is locally non-increasing at $x = 1$ and thus $-g'(1) \geq 0$. Since the sum for every row in matrix $D_{A_R}^1A_R$ equals 1, the Perron-Frobenius theorem [10] says that its largest eigenvalue is 1. From Eq. (6), we have
\[
-g'(1)\mathbb{R}(\mu) < -g'(1) < f(1), \quad \forall \mu \in \lambda(D_{A_R}^1A_R).
\]
That is, if $-g'(1) < f(1)$, then $B^* = 1$ is locally stable; if $-g'(1) > f(1)$, there exists at least one eigenvalue $\mu_0 \in \lambda(D_{A_R}^1A_R)$, say $\mu_0 = 1$, such that $-g'(1)\mathbb{R}(\mu_0) - f(1) > 0$, meaning that $B^* = 1$ is locally unstable.

To prove the second part, we observe that $f(0) = 0$ implies $H_0$ with $\sigma = 0$, namely that $B^* = 0$ is an equilibrium of (2). For $\sigma = 0$, Eq. (4) becomes
\[
\frac{d\delta B}{dt} = \left[ (1 - \sigma) \cdot f'(0)D_{A_B}^1A_B - 0 \cdot g'(0)D_{A_R}^1A_R \right] - \left[ f(0) + g(0) \right] I_0 \delta B
\]
\[
= \left[ f'(0)D_{A_B}^1A_B - g(0)I_0 \right] \delta B.
\]
Proposition 1 says that the sufficient condition for equilibrium $B^* = 0$ to be locally stable is
\[
f'(0)\mathbb{R}(\mu) < f'(0) < g(0), \quad \forall \mu \in \lambda(D_{A_B}^1A_B).
\]
(7)
Since $f(0) = 0$ and $f(x) \geq 0$ for $x \in [0, 1]$, $f(x)$ is locally non-decreasing at $x = 0$ and thus $f'(0) \geq 0$. Since the largest eigenvalue of $D_{A_B}^1A_B$ is 1, from Eq. (7) we have
\[
f'(0)\mathbb{R}(\mu) < f'(0) < g(0), \quad \forall \mu \in \lambda(D_{A_B}^1A_B).
\]
That is, if $f'(0) < g(0)$, then $B^* = 0$ is locally stable; if $f'(0) > g(0)$, there exists at least one eigenvalue $\mu_0 \in \lambda(D_{A_B}^1A_B)$, say $\mu_0 = 1$, such that $f'(0)\mathbb{R}(\mu_0) - g(0) > 0$, meaning that $B^* = 0$ is locally unstable.

In the special case $G_B = G_R$, namely $A_B = A_R$, we immediately obtain the following corollary of Proposition 1:

**Corollary 2.** Suppose hypothesis $H_0$ holds and $G_B = G_R = G$ (i.e., $A_B = A_R = A$). Let $\mu_1 = 1$ be the eigenvalue of $D_{A_B}^1A$ that has the smallest real part. If the attack-power and defense-power functions satisfy one of the following two conditions:

(i). $(1 - \sigma)f'(\sigma) - \sigma g'(\sigma) > 0$ and $f(\sigma) + g(\sigma) > 0$

(ii). $(1 - \sigma)f'(\sigma) - \sigma g'(\sigma) < 0$ and $f(\sigma) + g(\sigma) < 0$

If the attack-power and defense-power functions satisfy one of the two following conditions:

(i). $(1 - \sigma)f'(\sigma) - \sigma g'(\sigma) > 0$ and $f(\sigma) + g(\sigma) > 0$

(ii). $(1 - \sigma)f'(\sigma) - \sigma g'(\sigma) < 0$ and $f(\sigma) + g(\sigma) < 0$

$\mathbb{R}(\mu_1)$, then equilibrium $B^* = \sigma \in [0, 1]$ is locally stable.

### 3.2 Examples

**Example 1:** Stability effect of different defense-power functions vs. a fixed attack-power function. Suppose $G_B = G_R$ is an Erdős-Rényi (ER) random graph instance $G = (V, E)$ with $|V| = 2,000$ and edge probability $p = 0.005$ (i.e., every pair of nodes is connected with probability 0.005, independent of each other). We consider attack-power function $g(x) = 1 - x$ against the following four scenarios of defense-power function $f(x)$:

- **Scenario I:** $f(x) = x^2$, meaning that $B^* = 0$ is stable and $B^* = 1$ is unstable.
- **Scenario II:** $f(x) = x^2 + x$, meaning that $B^* = 0$ is unstable and $B^* = 1$ is stable.
- **Scenario III:** $f(x) = x^2 + \frac{1}{2} x$, meaning that $B^* = 0$ and $B^* = 1$ are stable, but $B^* = \frac{1}{2}$ is unstable.
- **Scenario IV:** $f(x) = -2x^2 + 2x$, meaning that $B^* = \frac{1}{2}$ is stable, but $B^* = 0$ and $B^* = 1$ are unstable.

Figure 2 plots the phase portraits of $\langle B_0(t) \rangle = \frac{1}{|V|} \sum_{v \in V} B_0(t)$, the portion of secure nodes. We observe that the simulation results confirm the analytic results. Specifically, Figure 2(a) shows that $\langle B_0(t) \rangle$ converges to $B^* = 0$ when $\langle B_0(0) \rangle < 1$ for all $v \in V$; Figure 2(b) shows that $\langle B_0(t) \rangle$ converges to $B^* = 1$ when $\langle B_0(0) \rangle > 0$ for all $v \in V$; Figure 2(c) shows that $\langle B_1(t) \rangle$ converges to $B^* = 1$ when $\langle B_1(0) \rangle > 0.5$ for all $v \in V$ and converges to $B^* = 0$ when $\langle B_1(0) \rangle < 0.5$ for all $v \in V$; Figure 2(d) shows that $\langle B_0(t) \rangle$ converges to $B^* = 0.5$ when $\langle B_0(0) \rangle < 1$ for all $v \in V$.

**Table 1:** The dynamics go to the respective equilibrium $B^*$ under some combinations of defense-power function $f(x)$ and attack-power function $g(x)$. 
perturbations, the overall cyber security dynamics never enter any persistent equilibrium. This offers one possible explanation why real-life cyber security is perhaps never in any equilibrium.

Figure 4: Phase portraits of the portion of secure nodes \( \langle B_v(t) \rangle \): \( f(x, \nu) = \nu x - 2x^2 \) and \( g(x) = (1 - 2x)^2 \).

Example 2: Stability effect of parameterized defense-power functions vs. a fixed attack-power function. Suppose \( G_B = G_R \) is an ER graph \( G = (V, E) \) with \( |V| = 2,000 \), but with edge probability \( p = 0.5 \). We consider the following parameterized defense-power function \( f(x, \nu) \) with parameter \( \nu \in (0, +\infty) \) and fixed attack-power function \( g(x) \):

\[
f(x, \nu) = \nu x - 2x^2, \quad g(x) = (1 - 2x)^2.
\]

Figure 4 plots the phase portraits of \( \langle B_v(t) \rangle \) with \( \nu = 0.5, 0.8, 0.85, 1, 1.5, 2 \), respectively. The portraits can be classified into three classes. Figures 4(a)-(4b) show that there is one stable equilibrium \( B^* = 0 \). Figure 4(c) shows that there are three equilibria \( B^* = 0, 0.38, 0.2 \), where the first two are stable but the last one is unstable. Figures 4(d)-(4f) show that there exist two equilibria \( B^* = 0, \sigma \) with \( \sigma > 0 \), where \( B^* = 0 \) is unstable and \( B^* = \sigma \) is stable. We observe that active cyber defense dynamics exhibit different phenomena with respect to different parameters. Moreover, we observe a sort of phase transition in parameter \( \nu \) when \( \nu \leq 0.8 \), the global cyber security state converges to \( B^* = 0 \) almost regardless of the initial value; when \( \nu \geq 1 \), the global cyber security state converges to some \( B^* = \sigma > 0 \) almost regardless of the initial value; when \( 0.8 < \nu < 0.85 < 1 \), the global cyber security state converges to some equilibrium dependent upon the initial value.

We summarize the discussion in this section into:

INSIGHT 1. Active cyber defense dynamics may rarely enter into any equilibrium because of perturbations to the global security state as caused by the manual cleaning of some compromised computers (Figure 2), and/or because of perturbations to the attack/defense power function as caused by the introduction of a new attack/defense method (Figures 3-4).
4. TRANSITION BETWEEN MULTIPLE ATTRAACTORS

We are now ready to precisely characterize the transition between the equilibria, which reflects the consequence/effect of the defender manipulating the initial global security state (e.g., manually cleaning up some compromised computers before launching active defense) and/or manipulating the attack/defense network structure (e.g., by changing the network access control policy to block/allow certain computers to communicate with certain other computers).

4.1 Transition Between the All-blue and All-red Equilibria

Under the conditions mentioned in Corollary 1, namely, \( f(0) = g(0) = 0 \), system (2) has two locally stable equilibria \( B^* = 1 \) and \( B^* = 0 \). Let \( B = [B_1, B_2, \ldots, B_n] \in [0,1]^n \) and \( R = 1 - B = [1 - B_1, 1 - B_2, \ldots, 1 - B_n] \in [0,1]^n \), where \( n = |V| \). For \( \tau_1^*, \tau_2^* \in (0,1) \), we define two sets \( \Xi_{G_B, \tau_1^*} \) and \( \Xi_{G_B, \tau_2^*} \) as follows:

\[
\Xi_{G_B, \tau_1^*} = \left\{ B \in [0,1]^n \mid \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u \geq \tau_1^*, \forall v \in V \right\}.
\]

\[
\Xi_{G_B, \tau_2^*} = \left\{ R \in [0,1]^n \mid \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} R_u \geq \tau_2^*, \forall v \in V \right\}.
\]

The following Theorem 1, whose proof is deferred to the Appendix, gives the transition between the all-blue and all-red equilibria by manipulating the initial state \( B(0) \).

**Theorem 1.** Let \( G_B = (V, E_B) \) and \( G_R = (V, E_R) \) be two arbitrary graphs. Suppose that \( f(\cdot) \) and \( g(\cdot) \) are continuous with \( f(0) = g(0) = 0 \).

**Case 1:** Suppose the attack-power and defense-power functions satisfy, \( \forall z \in [\tau_1^*,1) \) and \( \forall B \in \Xi_{G_B, \tau_1^*} \) and some \( \alpha > 0 \),

\[
f(z) > \alpha \cdot z,
\]

\[
f\left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u \right) + g\left( \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} R_u \right) \leq \alpha
\]

If initial value \( B(0) \in \Xi_{G_B, \tau_1^*} \), then \( \lim_{t \to \infty} B_v(t) = 1 \forall v \in V \).

**Case 2:** Suppose the attack-power and defense-power functions satisfy, \( \forall z \in [\tau_2^*,1) \) and \( \forall R \in \Xi_{G_R, \tau_2^*} \) and some \( \beta > 0 \),

\[
g\left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} R_u \right) \leq \beta
\]

If initial value \( R(0) \in \Xi_{G_R, \tau_2^*} \), then \( \lim_{t \to \infty} R_v(t) = 1 \forall v \in V \).

The cyber security meaning of Theorem 1 is: Under a certain condition (case 1), the defender needs to manipulate the initial global security state \( B(0) \) to belong to \( \Xi_{G_B, \tau_1^*} \) to make active defense \( 1\)-effective; this says what the defender should strive to do. Under certain other circumstances (case 2), the defender should make sure that the initial global security state \( B(0) \) does not cause \( R(0) = 1 - B(0) \in \Xi_{G_R, \tau_2^*} \), because in this regime active defense is \( 0\)-effective; this says what the defender should strive to avoid.

For the following two corollaries, we define

\[
\Xi_{G_B, \tau^*} = \left\{ B \in [0,1]^n \mid \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u > \tau, \forall v \in V \right\},
\]

\[
\Theta_{G_R, \tau^*} = \left\{ R \in [0,1]^n \mid \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} R_u < \tau, \forall v \in V \right\}.
\]

On one hand, the following Corollary 3 says that when \( \tau_1^* = \tau_2^* = \tau^* \), we obtain the same threshold for the transitions.

**Corollary 3.** Suppose \( f(\cdot) \) and \( g(\cdot) \) are continuous with \( f(0) = g(0) = 0 \). There exist constants \( \tau \in (0,1) \) and \( \alpha > 0 \) such that the following two conditions hold:

(i) The attack-power and the defense-power functions satisfy \( f(z) > \alpha \cdot z \) for any \( z \in (\tau^*,1) \) and for any \( B \in \Xi_{G_B, \tau^*} \)

\[
f\left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u \right) + g\left( \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} R_u \right) \leq \alpha
\]

(ii) The attack-power and the defense-power functions satisfy \( g(z) > \alpha(1 - z) \) for any \( z \in (0,\tau^*) \), and for any \( B \in \Theta_{G_R, \tau^*} \)

\[
f\left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u \right) + g\left( \frac{1}{\deg(v, G_R)} \sum_{u \in N_v, G_R} R_u \right) \leq \alpha
\]

If initial value \( B(0) \in \Xi_{G_B, \tau^*} \), then \( \lim_{t \to \infty} B_v(t) = 1 \forall v \in V \); if initial value \( B(0) \in \Theta_{G_R, \tau^*} \), then \( \lim_{t \to \infty} B_v(t) = 0 \forall v \in V \).

On the other hand, the following Corollary 4 makes a connection to [36], by accommodating Theorems 1, 5, 8 and 9 in [36] as a special case with \( G_B = G_R \) and \( \alpha = 1 \).

**Corollary 4.** Suppose \( G_B = G_R = G = (V, E) \) and \( f(\cdot) \) and \( g(\cdot) \) are continuous with \( f(0) = g(0) = 1 \). There exist \( \tau^* \in (0,1) \) and \( \alpha > 0 \) such that the attack-power and defense-power functions satisfy

\[
f(z) + g(z) \leq \alpha \forall z \in [0,1]
\]

and the defense-power function satisfy

\[
f(z) > \alpha \cdot z \forall z \in (\tau^*,1) \) and \( f(z) < \alpha \cdot z \forall z \in (0,\tau^*)
\]

If initial value \( B(0) \in \Xi_{G, \tau^*} \), then \( \lim_{t \to \infty} B_v(t) = 1 \forall v \in V \); if initial value \( B(0) \in \Theta_{G, \tau^*} \), then \( \lim_{t \to \infty} B_v(t) = 0 \forall v \in V \).
BER graph instances with cyber defense dynamics. A rigorous characterization, such as The-defense network structure can lead to substantial change in active
5. HOPF BIFURCATION

4.2 Example

We consider the transition between equilibria \( B^* = 0 \) and \( B^* = 1 \) as caused by varying the initial value \( B(0) \). We use two concrete
count defense-power and attack-power functions:

\[
f(x) = \frac{1}{e^{-10x} + 1}, \quad g(x) = 2(1 - x)^2,
\]

which are plotted in Figure 5(a). The graphs \( G_B \) and \( G_R \) are two ER graph instances with \( |V| = 2,000 \) and \( p = 0.5 \). We consider the transition induced by varying the initial value \( \langle B_n(0) \rangle \) between 0 and 1. Figure 5(b) shows that when \( \langle B_n(0) \rangle > 0.5 \), the dynamics converge to \( B^* = 1 \); when \( \langle B_n(0) \rangle < 0.5 \), the dynamics converge to \( B^* = 0 \).

The exploration in this section can be summarized as:

**INSIGHT 2.** A small change in the initial global security state, in the model parameters, in the attack network structure, or in the defense network structure can lead to substantial change in active cyber defense dynamics. A rigorous characterization, such as Theorem 1, can offer precise guidance on “what the defender should strive to do” and “what the defender should strive to avoid” (e.g., how to manipulate the dynamics to benefit the defender rather than the attacker).

5. HOPF BIFURCATION

We consider Hopf bifurcation near equilibrium \( B^* = \sigma \in (0, 1) \) under condition \((1 - \sigma) \cdot f(\sigma) = \sigma \cdot g(\sigma)\). Recall that the stability of \( B^* = \sigma \in (0, 1) \) depends on \( \lambda_1(M) \), where \( M \), as defined in Eq. (3), is the Jacobian matrix of system (2). In the rest of the paper, we may simplify the notation \( \lambda_1(M) \) as \( \lambda_1 \) unless there is potential ambiguity.

Consider differentiable defense-power and attack-power functions \( f(\sigma, \nu) \) and \( g(\sigma, \nu) \) with parameter \( \nu \). Suppose \( \frac{\partial f}{\partial \nu} \) and \( \frac{\partial g}{\partial \nu} \) all depend on \( \nu \). Consider the following critical condition for Hopf bifurcation:

\[
\Re(\lambda_1) = 0 \quad \text{and} \quad \Im(\lambda_1) \neq 0.
\]

It is known that if (13) holds for some \( \nu = \nu^* \), \( \lambda_1(\nu^*) \) is differentiable in \( \nu \), and \( \frac{\partial \lambda_1}{\partial \nu} \neq 0 \) at \( \nu = \nu^* \), then system (2) exhibits Hopf bifurcation [24]. Therefore, we need to find the critical value \( \nu^* \). For this purpose, we adopt the approach described in [20] to investigate how \( \lambda_1 \) depends on the permutation to \( M \), namely to conduct a perturbation spectral analysis to compute the perturbation to \( \lambda_1 \), denoted by \( \delta \lambda_1 \), as caused by perturbation to \( M \), denoted by \( \delta M \).

5.1 How to Estimate \( \delta \lambda_1 \)

Let \( x_1 \) be the eigenvector of \( M \) associated to eigenvalue \( \lambda_1 \), namely, \( M x_1 = \lambda_1 x_1 \). For perturbation \( \delta M \) to \( M \), \( M + \delta M \) can be described as \( M(\nu) + M(\nu)\delta \nu \). The perturbation to \( M \) causes perturbation \( \delta \lambda_1 \) to \( \lambda_1 \) and perturbation \( \delta x_1 \) to \( x_1 \). That is,

\[
(M + \delta M)(x_1 + \delta x_1) = (\lambda_1 + \delta \lambda_1)(x_1 + \delta x_1).
\]

By ignoring the second-order term, we obtain

\[
M\delta x_1 + \delta M x_1 = \lambda_1 \delta x_1 + \delta \lambda_1 x_1.
\]

By multiplying both sides of Eq. (14) with the left eigenvector \( y_1 \) corresponding to \( \lambda_1 \), we obtain

\[
y_1^T M \delta x_1 + y_1^T \delta M x_1 = y_1^T \lambda_1 \delta x_1 + y_1^T \delta \lambda_1 x_1,
\]

\[
y_1^T \lambda_1 \delta x_1 + y_1^T \delta M x_1 = y_1^T \lambda_1 \delta x_1 + y_1^T \delta \lambda_1 x_1,
\]

\[
y_1^T \delta M x_1 = y_1^T \delta \lambda_1 x_1.
\]

As a result, we can estimate \( \delta \lambda_1 \) as

\[
\delta \lambda_1 = \frac{y_1^T \delta M x_1}{y_1^T x_1},
\]

where \( \delta M \) can be estimated depending on whether the perturbation is to the attack and/or defense power (Case A below) or to the attack/defense network structure (Case B below).

**Case A:** \( \delta M \) is caused by perturbation to attack- and/or defense power. Suppose the perturbation is imposed on parameter \( \nu \) in the attack-power and defense-power functions \( f(\sigma, \nu) \) and \( g(\sigma, \nu) \), where \( \frac{\partial f}{\partial \nu} \) and \( \frac{\partial g}{\partial \nu} \) depend on \( \nu \) as mentioned above. The cyber security meanings of such perturbations is (for example) that new attack and/or defense techniques are introduced. Note that

\[
\delta M(\nu) = \left\{ - \left[ (1 - \sigma) \frac{\partial f}{\partial \nu} D_{A_B}^{-1} A_B - \sigma \frac{\partial g}{\partial \nu} D_{A_R}^{-1} A_R \right] - \left[ \frac{\partial f}{\partial \nu} + \frac{\partial g}{\partial \nu} \right] I_n \right\} \delta \nu.
\]

In the special case \( G_B = G_R = G \) (i.e., the adjacency matrix \( A_B = A_R = A \)), we have

\[
M = [(1 - \sigma) f'(\sigma) - \sigma g'(\sigma)] D_{A}^{-1} A - [f(\sigma) + g(\sigma)] I_n,
\]
the eigenvalues of $M$ are $\{1 - \sigma \} f'(\sigma) - \sigma g'(\sigma) \} \mu - [f(\sigma) + g(\sigma)] I_n$, and the perturbation can be rewritten as

$$
\delta M(\nu) = \left\{ \left( 1 - \sigma \right) \frac{\partial f(\sigma, \nu)}{\partial \nu} - \sigma \frac{\partial g(\sigma, \nu)}{\partial \nu} \right\} \delta A^1 A - \left[ \frac{\partial f(\sigma, \nu)}{\partial \nu} + \frac{\partial g(\sigma, \nu)}{\partial \nu} \right] I_n \delta \nu.
$$

Hence, (15) becomes

$$
\delta \lambda_1 = y_1^T \left\{ \left( 1 - \sigma \right) \frac{\partial f(\sigma, \nu)}{\partial \nu} - \sigma \frac{\partial g(\sigma, \nu)}{\partial \nu} \right\} \delta A^1 A - \left[ \frac{\partial f(\sigma, \nu)}{\partial \nu} + \frac{\partial g(\sigma, \nu)}{\partial \nu} \right] I_n \delta \nu \cdot x_1
$$

Case B: $\delta M$ is caused by perturbation to attack and/or defense network structure. Suppose the perturbation is imposed on $G_B = (V, E_B)$ and/or $G_R = (V, E_R)$ by adding/deleting edges. The cyber security meaning of such perturbations is that the network is disrupted (e.g., edges are deleted by the attacker, or security policies have changed) and then edges are added by the defender. We assume that the number of added/deleted edges is small (compared with $|E_B|$ and $|E_R|$, respectively) so that we can approximately treat $\delta M$ as a small perturbation. Let $C_B = D_{A_B}^{-1} A_B$ and $C_R = D_{A_R}^{-1} A_R$. Perturbations to $A_B$ and $A_R$ lead to $A_B + \delta A_B$ and $A_R + \delta A_R$, respectively. Correspondingly, we obtain the perturbations to $C_B$ and $C_R$:

$$
\delta C_B = D_{A_B}^{-1} (A_B + \delta A_B) - D_{A_B}^{-1} A_B,
$$

$$
\delta C_R = D_{A_R}^{-1} (A_R + \delta A_R) - D_{A_R}^{-1} A_R.
$$

Then, the perturbation to Jacobian matrix $M$ is

$$
\delta M = \left( 1 - \sigma \right) f'(\sigma) \delta C_B - \sigma g'(\sigma) \delta C_R.
$$

From (15), we have

$$
\delta \lambda_1 = y_1^T \left\{ \left( 1 - \sigma \right) f'(\sigma) \delta C_B - \sigma g'(\sigma) \delta C_R \right\} x_1.
$$

Note that in the special case $G_B = G_R = G$ (i.e., $A_B = A_R = A$) with perturbations $\delta C_B = \delta C_R$, we have

$$
\delta M = \left[ \left( 1 - \sigma \right) f'(\sigma) - \sigma g'(\sigma) \right] \delta C,
$$

$$
\delta \lambda_1 = y_1^T \left[ \left( 1 - \sigma \right) f'(\sigma) - \sigma g'(\sigma) \right] \delta C x_1.
$$

5.2 Example: Hopf Bifurcation Induced by Perturbation to Parameter

In order to show that Hopf bifurcation can happen, we consider an ER graph $G_B = G_R = G = (V, E)$ with $|V| = 2000$ and edge probability $p = 0.005$. Let $\mu_1$ denote the eigenvalue of $D_A^{-1} A$ with the smallest real part, where $A$ is the adjacency matrix of $G$. For the ER graph, we have $\Re(\mu_1) = -0.3448$. We consider the following defense-power and attack-power functions:

$$
f(x) = -4x^2 + 4x, \quad g(x, \nu) = \left( ux - \frac{\nu}{2} \right)^2,
$$

where $f(x)$ does not depend on $\nu$. Recall that under condition $(1 - \sigma) f(\sigma) = \sigma g(\sigma)$, there exists equilibrium $B^* = \sigma \in (0, 1)$.

When $\nu = 3$, we have homogeneous equilibrium $B^* = 0.7$, which is locally stable according to the second condition in the first part of Corollary 2:

$$
(1 - \sigma) f'(\sigma) - \sigma g'(\sigma, 3) = -3 < 0,
$$

$$
(1 - \sigma) f'(\sigma) - \sigma g'(\sigma, 3) = -0.4 < \Re(\mu_1) = -0.3448.
$$

When $\nu = 4$, we have homogeneous equilibrium $B^* = 0.6667$, which is locally unstable according to the second condition in the second part of Corollary 2:

$$
(1 - \sigma) f'(\sigma) - \sigma g'(\sigma, 4) = -4 < 0
$$

$$
(1 - \sigma) f'(\sigma) - \sigma g'(\sigma, 4) = -0.3333 > \Re(\mu_1) = -0.3448.
$$

Therefore, there is a critical value between $\nu = 3$ and $\nu = 4$, at which $\Re(\lambda_1(M)) = 0$. By conducting 100 independent simulation runs of $\nu \in [3, 4]$ with step-length 0.01, we find the critical value $\nu = 3.8$ and the corresponding equilibrium $B^* = 0.6724$, where

$$
(1 - \sigma) f'(\sigma) - \sigma g'(\sigma, 3.8) = 7.381 < 0,
$$

$$
(1 - \sigma) f'(\sigma) - \sigma g'(\sigma, 3.8) = -0.3448 = \Re(\mu_1).
$$

Figure 6(a) plots the periodic trajectory of $\{B_n(t)\}$ when $\nu = 4 > 3.8$, which surrounds equilibrium $B^* = 0.6724$. Figure 6(b) plots the periodic trajectory of $\{B_n(t)\}$ when $\nu = 5.05 > 3.8$. Figure 6(c) plots the bifurcation diagram with respect to $\nu \in (3, 5.5)$. We observe that when $\nu \in (5, 5.5)$, there are not only two-periodic trajectories, but also $k$-periodic trajectories ($k > 2$). In summary, the periodic trajectories exhibit the period-doubling cascade phenomenon.

5.3 Example: Hopf Bifurcation Induced by Perturbation to Attack/Defense Network Structures

For the purpose of demonstrating the bifurcation phenomenon caused by perturbation to network structures, we use two randomly generated ER graph examples $G_B = (V, E_B)$ and $G_R = (V, E_R)$, both with $|V| = 2000$ and $p = 0.005$. The average degree is 10.0565 for $G_B$ and 11.1865 for $G_R$. We use the following defense-power and attack-power functions:

$$
f(x) = -4x^2 + 4x, \quad g(x, \nu) = \left( ux - \frac{\nu}{2} \right)^2 \quad \text{with} \quad \nu = 6.
$$

We perform 100 iterations of operations to $G_R$ as follows: during each of the first 50 iterations, we delete 226 edges (or 1% of the edges in the original $E_R$) chosen independently and uniformly at random; during each of the following 50 iterations, we add 226 edges chosen independently and uniformly random among all the unconnected edges. That is, we delete and then add 50% edges of the original $E_R$.

Figure 7 demonstrates that the period-doubling cascade phenomenon appears and finally leads to chaos after deleting more than 36% edges and before adding 14% edges. We observe that eventually the diagram becomes stable after adding the same number of edges as those deleted. (Note that Figure 7 is not symmetric because the added edges are random and in general are different from the edges that are deleted.)

The following insight summarizes the exploration of this section.

INSIGHT 3. Active cyber defense dynamics can exhibit Hopf bifurcation, when the attack/defense power varies in certain parameter regimes and/or when the attack/defense network structure varies.
in certain patterns. These situations are “unmanageable” because it would be infeasible, if not impossible, to estimate the global security state in real-time. Therefore, the defender must strive to avoid such unmanageable situations by manipulating the dynamics carefully (e.g., by disrupting the bifurcation condition or containing the attack-power of the adversary).

6. CHAOS

Figure 6(c) shows that the number of periodic points increase with parameter $\nu$, which hints that system (2) can exhibit the chaos phenomenon. To see this, we consider the case $G_B = G_R$. In this case, system (2) becomes

$$\frac{d B_v(t)}{dt} = f \left( \frac{1}{\deg(v,G)} \sum_{u \in N_v,G} B_u(t) \right) \left[ 1 - B_v(t) \right] - g \left( \frac{1}{\deg(v,G)} \sum_{u \in N_v,G} B_u(t) \right) B_v(t).$$

Let $F(B_v(0), t)$ denote the right-hand part. Consider $B_v(0)$ and $B_v(0) + \varepsilon_v(0)$ for all $v \in V$, where $\varepsilon_v(0) \in \mathbb{R}^n$ is a small perturbation to the initial point $B_v(0)$. Then, we have $\forall v \in V$,

$$\varepsilon_v(t) = F(B_v(0) + \varepsilon_v(0), t) - F(B_v(0), t) = DF(B_v(0), t) \cdot \varepsilon_v(0),$$

where $DF(B_v(0), t)$ is the Jacobian matrix of the map $F$ at time $t$. By the QR decomposition of matrix $\varepsilon(t) = [\varepsilon_1(t), \varepsilon_2(t), \cdots, \varepsilon_n(t)]$ where $n = |V|$, we obtain matrix

$$\varepsilon(t) = q(t) \cdot r(t),$$

where $q(t)$ is an orthogonal matrix and $r(t)$ is an upper triangular matrix. Note that $\varepsilon(t) = q(t)$ and the diagonal element $\lambda_i(t)$ of $r(t)$ at time $t$ is the exponential magnification, where $i \in \{1, 2, \cdots, n\}$. Thus, the average rate of divergence or convergence of the two trajectories $\{F(B_v(0), t) | t \geq 0\}$ and $\{F(B_v(0) + \varepsilon_v(0), t) | t \geq 0\}$ for all $v \in V$ is defined by

$$L_i = \lim_{t \to +\infty} \frac{1}{t} \ln \lambda_i(t),$$

where $L_i$ for $i = 1, 2, \cdots, n$ are the Lyapunov characteristic exponents. It is known [24] that under some mild conditions, the

Figure 6: Limit cycle and Hopf bifurcation diagram, where $\langle B_v \rangle$ are the extremum points of $\langle B_v(t) \rangle$ in time period $t \in (1000, 2000)$.

Figure 7: Hops bifurcation induced by perturbation to the network structure.
above limit exists and is finite for almost all initial values $B(0) = [B_1(0), B_2(0), \cdots, B_n(0)]$ and for almost all matrices $\varepsilon(0)$. Note that $\text{MLE} = \max_{1 \leq i \leq n} L_i$ indicates whether the dynamical system is chaotic or not. More specifically, when $\text{MLE} > 0$, a small perturbation to the initial value will lead to an exponential separation and therefore leads to the chaos phenomenon.

Example. Consider an ER graph instance $G_B = G_R$ with $|V| = 2,000$ and $p = 0.005$, and the following defense-power and attack-power functions:

$$f(x) = -4x^2 + 4x, \ g_\nu(x) = \left(\nu x - \frac{\nu}{2}\right)^2.$$ 

![Maximal Lyapunov exponent vs. $\nu$](image1.png)

(a) MLE with $\nu$: MLE $> 0$ indicates chaos.

![Graph of $B_\nu(t)$ for $\nu = 8$](image2.png)

(b) $\{B_\nu(t)\}$ for $\nu = 8$ exhibits chaos.

Figure 8: Active cyber defense dynamics exhibit the chaos phenomenon: $G_B = G_R$ with $|V| = 2,000$ and $p = 0.005$.

Figure 8(a) plots the MLE with respect to $\nu$. We observe that $\text{MLE} > 0$ when $\nu > 5$, meaning that system (17) exhibit chaos for $\nu > 5$. Figure 8(b) plots the phase portrait of $\{B_\nu(t)\}$ (i.e., the average of the $B_\nu(t)$’s for all $v \in V$) when $\nu = 8$, which hints the emergence of chaos. This means that the defender should strive to avoid the parameter regime $\nu > 5$. This leads to the following:

**Insight 4.** Active cyber defense dynamics can be chaotic, meaning that it is impossible to predict the global cyber security state because it is too sensitive to the accuracy of the estimated initial global security state. Therefore, the defender must strive to avoid such unmanageable situations (e.g., by disrupting the attacks to assure $\nu \leq 5$ in the above example).

7. **RELATED WORK**

Cybersecurity Dynamics is a framework for modeling and quantifying cyber security from a holistic perspective (rather than modeling and analyzing security of components or building-blocks) [34, 35, 36, 17]. This framework builds on a large body of literature across Computer Science, Mathematics and Statistical Physics (cf. [7, 4, 33, 37, 17, 39, 29, 6, 3, 28, 23, 11, 12] and the references therein), which can be further traced back to the century-old studies on biological epidemic models [19, 13, 8].

As a specific kind of cybersecurity dynamics, active cyber defense dynamics were first rigorously modeled and studied in [36], despite that the idea of active defense has been discussed and debated for many years [14, 31, 18, 16, 26, 30, 1, 2]. We move a significant step beyond [36], by separating the attack network structure from the defense network structure, and by considering more general attack and defense power functions. To the best of our knowledge, we are the first to show that bifurcation and chaos are relevant in the cyber security domain, and to discuss the cyber security implications of these phenomena. Following [36], Lu et al. [17] investigate optimal active defense strategies in the Control-Theoretic and Game-Theoretic frameworks. Our study is complementary to [17] as we leave it to future work to investigate optimal strategies in our setting.

It is worth mentioning that models of Lotka-Volterra type [9] capture the predator-prey dynamics, which are however different from the active cyber defense dynamics. Active cyber defense dynamics may be seen as the non-linear generalization of the so-called Voter model in complex networks [25, 15]. Somewhat related to our work is [5], which considers chaotic dynamics in discrete-time limited imitation contagion model on random networks.

8. **CONCLUSION**

We have explored the rich phenomena that can be exhibited by active cyber defense dynamics. To the best of our knowledge, our study is the first to show that bifurcation and chaos are relevant in the cyber security domain. The implication is of high practical value: In order to make cyber security measurement and prediction feasible, the defender must manipulate the cyber security dynamics to avoid these unmanageable situations.

Interesting problems for future research include: First, we need to characterize non-homogeneous equilibria as we only focused on homogeneous equilibria. Second, we need to characterize which graph structure is more advantageous to the other (e.g., $G_B$ is ER graph but $G_R$ is power-law graph). Third, we need to explore the chaos phenomenon further (e.g., multi-direction chaos). Fourth, we need to systematically validate the models.

APPENDIX

Now we prove Theorem 1.

PROOF. We prove the theorem in the first statement with $B(0) \in \Xi_{G_B, \tau_1}$, and the second statement with $R(0) \in \Xi_{G_R, \tau_2}$ can be proved similarly.

First, we see that $g(1) = 0$ implies that $B^* = 1$ is an equilibrium of (2) according to Proposition 1. Define

$$V_t = \arg\min_{u \in V} B_u(t) = \left\{ u \mid B_u(t) = \min_{u \in V} B_u(t) \right\}$$

for $t \geq 0$. Since the case $\min_{u \in V} B_u(0) = 1$, namely $B_u(t) = 1$ for all $u \in V$ and $t \geq 0$, is trivial, we assume $\min_{u \in V} B_u(0) < 1$ without loss of any generality. For any $v(0) \in V_0$, the given condition (10) implies

$$\frac{1}{\deg(v(0), G_B)} \sum_{u \in N(v(0), G_B)} B_u(0) \geq \tau_1,$$

and thus we have

$$f \left( \frac{1}{\deg(v(0), G_B)} \sum_{u \in N(v(0), G_B)} B_u(0) \right) \geq \alpha \cdot \frac{1}{\deg(v(0), G_B)} \sum_{u \in N(v(0), G_B)} B_u(0).$$
where "=" holds only when \( \frac{1}{\deg(v(0), G_B)} \sum_{u \in N_v(0), G_B} B_u(0) = 1 \). Let \( t = 0 \) and \( v = v(0) \). Using Eq. (2) and condition (11), we have
\[
\frac{dB_v(0)(t)}{dt} \bigg|_{t=0} = f \left( \frac{1}{\deg(v(0), G_B)} \sum_{u \in N_{v(0)}, G_B} B_u(0) \right) \left[ 1 - B_{v(0)}(0) \right] - g \left( \frac{1}{\deg(v(0), G_B)} \sum_{u \in N_{v(0)}, G_B} B_u(0) \right) B_{v(0)}(0) \geq f \left( \frac{1}{\deg(v(0), G_B)} \sum_{u \in N_{v(0)}, G_B} B_u(0) \right) - \alpha B_{v(0)}(0) \geq \alpha \left( B_{v(0)}(0) - B_{v(0)}(0) \right) \geq 0. \quad (17)
\]

Since the equality signs hold in the two inequalities in Eq. (17) only when \( \min_{u \in V} B_u(0) = 1 \), which corresponds to the trivial case mentioned above, we conclude that \( \min_{u \in V} B_u(t) \) strictly increases in a small time interval starting at \( t = 0 \) except for the trivial case.

Let \( \tau_1^* > \tau_1^* \) such that
\[
\frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(0) > \tau_1^* \quad \text{for all } v \in V.
\]
We now show that \( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) > \tau_1^* \) for all \( t > 0 \) and for all \( v \in V \). Let \( t_0 \) be the first time that \( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) = \tau_1^* \) for some \( v \in V \), i.e.,
\[
t_0 = \inf \left\{ t \left| \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) > \tau_1^* \forall t \in [0, \tau), \forall v \in V \right. \right\}.
\]
We show \( t_0 = +\infty \). Suppose \( t_0 < +\infty \). Let \( V^* \) be the node set such that for each \( v \in V^* \), \( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) \) reaches \( \tau_1^* \) for the first time. Then, for some \( v^* \in V^* \), we know that \( \frac{1}{\deg(v^*, G_B)} \sum_{u \in N_{v^*}, G_B} B_u(t) \) is not increasing at \( t = t_0 \). However, it can be shown that
\[
\frac{dB_v(t)}{dt} \bigg|_{t=t_0} = f \left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) \right) \left[ 1 - B_{v(t)}(t) \right] - g \left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) \right) B_{v(t)}(t) \geq f \left( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) \right) - \alpha B_{v(t)}(t) \geq \alpha \left( B_{v(t)}(t) - B_{v(t)}(t) \right) \geq 0,
\]
where the equality signs hold only for the trivial case as in the case of Eq. (17) mentioned above (i.e., in all other cases the inequalities are strict). So we reach a contradiction, which means \( t_0 = +\infty \). Owing to \( \tau_1^* > \tau_1^* \), we have \( \frac{1}{\deg(v, G_B)} \sum_{u \in N_v, G_B} B_u(t) > \tau_1^* \) for all \( t > 0 \). That is, \( B(t) \in [0, \tau_1^*] \) for all \( t \).

Let \( t_1 \) be the maximum time that \( \min_{v \in V} B_v(t) \) is strictly increasing, i.e.,
\[
t_1 = \sup \left\{ t \left| \min_{v \in V} B_v(t) \right. \right| \text{is strictly increasing in } [0, t] \}.
\]
We show that \( t_1 = +\infty \). Suppose that \( t_1 \) is finite, meaning that \( \min_{v \in V} B_v(t) \) is not increasing at time \( t = t_1 \). Since it holds that \( \min_{v \in V} B_v(t_1) > \min_{v \in V} B_v(0) > \tau_1^* \), by replacing \( B(0) \) with \( B(t_1) \), we have
\[
f \left( \frac{1}{\deg(v(t_1), G_B)} \sum_{u \in N_{v(t_1)}, G_B} B_u(t_1) \right) - \alpha B_{v(t_1)}(t_1) \geq \alpha \left( \frac{1}{\deg(v(t_1), G_B)} \sum_{u \in N_{v(t_1)}, G_B} B_u(t_1) - B_{v(t_1)}(t_1) \right) \geq 0,
\]
where are inequalities are strict except for the trivial case — as discussed in the case of Eq. (17). That is, \( \min_{v \in V} B_v(t) \) strictly increases at \( t = t_1 \), which contradicts with the definition of \( t_1 \). Therefore, we have \( t_1 = +\infty \) and \( \min_{v \in V} B_v(t) \) is strictly increasing in \( t \in [0, +\infty) \).
In order to show \( \lim_{t \to \infty} B_v(t) = 1 \) for all \( v \in V \), we will prove that \( \lim_{t \to \infty} \min_{v \in V} B_v(t) = 1 \) for \( \lim_{t \to \infty} \min_{v \in V} B_v(t) \leq \lim_{t \to \infty} B_v(t) \). Since \( B_v(t) \) is the probability that node \( v \in V \) is blue at time \( t \), we have \( 0 \leq B_v(t) \leq 1 \) for all \( v \in V \). Hence \( \lim_{t \to \infty} \min_{v \in V} B_v(t) \) exists. Suppose for the sake of contradiction that \( \lim_{t \to \infty} \min_{v \in V} B_v(t) < 1 \), meaning \( \min_{v \in V} B_v(t) < 1 \) for all \( t \) due to its strict increasing monotonicity. For any \( v \in V \), under the condition that Eq. (10) holds, there exists \( \varepsilon > 0 \) such that \( f(B_v(t)) - \alpha B_v(t) > \varepsilon \) for all \( t \).
Since \( \min_{v \in V} B_v(t) \) is strictly increasing for \( t \in [0, +\infty) \), there exists \( T > 0 \) such that
\[
\frac{dB_v(t)}{dt} \bigg|_{t=t_1} = f \left( \frac{1}{\deg(v(t), G_B)} \sum_{u \in N_{v(t)}, G_B} B_u(t) \right) \left[ 1 - B_{v(t)}(t) \right] - g \left( \frac{1}{\deg(v(t), G_B)} \sum_{u \in N_{v(t)}, G_B} B_u(t) \right) B_{v(t)}(t) \geq f \left( B_{v(t)}(t) \right) - \alpha B_{v(t)}(t) > \varepsilon,
\]
for all \( t > T \). This leads to
\[
B_v(t) > B_v(T) + \varepsilon(t - T).
\]
Since \( \min_{v \in V} B_v(t) = B_v(t) \to \infty \) as \( t \to \infty \), it contradicts with \( B_v(t) \leq 1 \). Therefore, we conclude \( \lim_{t \to \infty} \min_{v \in V} B_v(t) = 1 \) and \( \lim_{t \to \infty} B_v(t) = 1 \).
